**Oxidative Stress in Arterial Hypertension**

**Role of NAD(P)H Oxidase**

*Abstract*—Increased vascular reactive oxygen species production, especially superoxide anion, contributes significantly in the functional and structural alterations present in hypertension. An enhanced superoxide production causes a diminished NO bioavailability by an oxidative reaction that inactivates NO. Exaggerated superoxide levels and a low NO bioavailability lead to endothelial dysfunction and hypertrophy of vascular cells. It has been shown that the enzyme NAD(P)H oxidase plays a major role as the most important source of superoxide anion in vascular cells. Several experimental observations have shown an enhanced superoxide generation as a result of the activation of vascular NAD(P)H oxidase in hypertension. Although this enzyme responds to stimuli such as vasoactive factors, growth factors, and cytokines, some recent data suggest the existence of a genetic background modulating the expression of its different components. New polymorphisms have been identified in the promoter of the p22phox gene, an essential subunit of NAD(P)H oxidase, influencing the activity of this enzyme. Genetic investigations of these polymorphisms will provide novel markers for determination of genetic susceptibility to oxidative stress in hypertension. (*Hypertension*. 2001;38:1395-1399.)

**Key Words:** angiotensin II • genetics • hypertension, arterial • stress • free radicals

Large amounts of reactive oxygen species (ROS), resulting from oxygen, are produced in vascular cells, including superoxide anion (·O₂⁻) and hydrogen peroxide (H₂O₂), and act as important intracellular signals. Oxidative stress describes the injury caused to cells by the oxidizing of macromolecules resulting from increased formation of ROS and/or decreased antioxidant reserve. Recent works have reported that all types of vascular cells generate ROS. A growing number of reports have provided a critical role for oxidative stress in the pathogenesis of cardiovascular diseases, including hypertension.¹

An enhanced production of ROS contributes to the dysregulation of physiological processes, which leads to structural and functional alterations in hypertension.² Two characteristic alterations of the vascular wall in hypertension are endothelial dysfunction and vascular smooth muscle cell (VSMC) hypertrophy. An enhanced production of ROS causes a loss of NO bioavailability, which impairs endothelial function, causing (among others) a decreased endothelium-dependent vasodilation.³ Among these ROS, ·O₂⁻ is critically involved in the breakdown of NO.⁴ Thus, a diminished availability of NO can be the result of a decreased activity from the NO-production pathway or the result of an increase in the oxidative inactivation of NO by ·O₂⁻. Recently, we have shown that endothelial dysfunction is associated with an excess of ·O₂⁻ generation rather than a diminished NO production in the aorta of adult spontaneously hypertensive rats (SHR).⁵ The presence of unpaired electrons causes ·O₂⁻ to be chemically unstable and highly reactive. The reaction of ·O₂⁻ with NO leads to the production of peroxynitrite,⁶ a potent oxidant believed to be responsible for tissue injury. Peroxynitrite induces the oxidation of proteins, DNA, and lipids in vascular cells.⁷ On the other hand, recent findings suggest that increased ROS may stimulate VSMC hypertrophy and hyperplasia.⁸ Li et al⁹ has shown that ·O₂⁻ induces the proliferation of VSMCs, and Zafari et al¹⁰ has proposed a role for ·O₂⁻ and H₂O₂ in angiotensin II–induced VSMC hypertrophy. ROS are also involved in several signal pathways and in the activation of redox-sensitive transcriptional factors, such as nuclear factor (NF)-κB.¹¹ It has been shown recently that angiotensin II activates NF-κB in VSMCs.¹² Furthermore, NF-κB has been implicated in the transcription of a number of vascular genes.¹³ Finally, NF-κB seems to play a pivotal role in angiotensin II–stimulated ROS generation and inflammatory mechanisms (see review¹⁴).

NAD(P)H oxidase, which is to some extent similar to the previously reported neutrophil NADPH oxidase, is the most important source of -O_2^- in vascular cells. The structure and function of this vascular oxidase has been recently reviewed. At present, response to extracellular NAD(P)H is one of the major unanswered questions concerning membrane orientation and function of this oxidase. Vascular NAD(P)H oxidase consists of a cytochrome b558, composed of p22^phox and gp91^phox subunits and 3 cytosolic components, p47^phox, p67^phox, and rac. The Table summarizes the expression of these components in vascular cells. Transfection of antisense p22^phox demonstrated this subunit of the cytochrome to be essential for functionality of NAD(P)H oxidase. Disruption of gp91^phox and p47^phox subunits lowers vascular -O_2^- production, without significant alterations in basal blood pressure. Thus, the existence of compensatory mechanisms regulating blood pressure in this knockout mouse cannot be discarded. Although the gp91^phox subunit is absent in VSMCs, the presence of functional isoforms, Nox1 and Nox4, has been reported. Recently, it has been shown that Nox1 mediates angiotensin II–induced -O_2^- formation and redox-sensitive signaling pathways in VSMCs. Vascular NAD(P)H oxidase is a constitutive enzyme, but it can be regulated by humoral factors, such as angiotensin II, platelet-derived growth factor, thrombin, tumor growth factor-α, and glucocorticoids, and hemodynamic forces, including laminar and oscillatory shear stress.

NAD(P)H Oxidase in Experimental Hypertension

Angiotensin II–Induced Hypertension

Rajagopalan et al demonstrated that chronic infusion of angiotensin II in rats resulted in hypertension in correlation with an increased NAD(P)H oxidase-derived -O_2^- generation. In the same study, these alterations were corrected by pretreatment of the rats with losartan. Fukui et al reported that increased activity of NAD(P)H oxidase in angiotensin II–induced hypertension activated NAD(P)H oxidase by up-regulating the p22^phox mRNA levels, a critical component of this oxidase. Infusion of recombinant heparin-binding superoxide dismutase (SOD) decreased both blood pressure and p22^phox mRNA expression.

Recent evidence also suggests the involvement of other subunits in angiotensin II–induced hypertension. Thus, in aortas from angiotensin II–infused mice, there is an increased NAD(P)H-driven -O_2^- production concomitant with increased protein levels of p67^phox and gp91^phox subunits that is associated with the elevation of blood pressure. Furthermore, these angiotensin II–induced increases were normalized by simultaneous treatment with losartan.

DOCA-Salt and Renovascular Hypertension

Somers et al showed an enhanced vascular -O_2^- production associated with impaired endothelium-dependent relaxation in deoxycorticosterone acetate (DOCA)-salt rats, a hypertension model characterized by a low plasma renin activity. Recently, Wu et al have reported that the enhanced -O_2^- production present in the aorta of DOCA-salt hypertensive rats is associated with an increased NADH oxidase activity. It seems that this increased oxidase activity is independent of the rise in blood pressure. It has been suggested that an increased vascular angiotensin II release as a consequence of nephrectomy is the origin of the increased NADH oxidase activity in these rats.

Renovascular hypertension in the 2-kidney, 1-clip rat model depends on an increase in circulating angiotensin II levels. In this model, NO production is increased, and a potential role for -O_2^- in enhanced NO breakdown has been suggested. Heitzer et al showed an increased aortic -O_2^- generation in this hypertension model associated with an overactivity of NAD(P)H oxidase. Although the mechanism whereby angiotensin II activates NAD(P)H oxidase is still unclear, it might involve a protein kinase C–dependent process.

Genetic Hypertension

Several works have recently provided evidence confirming the pathophysiological function of ROS in the SHR. Suzuki et al showed an increased -O_2^- generation in venules and arterioles in these hypertensive rats. Furthermore, Nakazono et al demonstrated that administration within the vessel wall of heparin-binding SOD normalized the blood pressure of SHR. Recently, we reported an enhanced NAD(P)H oxidase–driven -O_2^- production associated with an upregulated p22^phox mRNA expression in the aorta of adult SHR with endothelial dysfunction and vascular wall hypertrophy.

In the same work, NAD(P)H oxidase–driven -O_2^- production was not increased in young SHR, which discards a critical role of hypertension in the regulation of oxidase. In this regard, it has been reported that in norepinephrine-induced hypertension, neither -O_2^- production nor NADH oxidase is increased. Interestingly, we found that both p22^phox mRNA expression and NAD(P)H oxidase activity were normalized in adult SHR treated with the angiotensin II type 1 (AT1) receptor antagonist irbesartan. This suggests a critical role of angiotensin II in the upregulation of this oxidase in the adult SHR. This possibility is further supported by the fact that enhanced expression of both AT1 receptor and ACE have been reported in vessels of adult SHR. As a consequence of an overactivity of the renin-angiotensin system, changes in the degree of activation of vascular cells can regulate p22^phox expression. In this regard, we observed that differences in the VSMC phenotype were correlated with changes in the p22^phox gene promoter activity. Thus, p22^phox gene promoter activity was increased in VSMCs isolated from adult SHR compared with those obtained from normotensive Wistar-Kyoto rats (WKY).
Morphisms in the promoter region of the p22phox gene might contribute to the upregulation of p22phox in the vessel wall of SHR. Taken together, these findings suggest that besides changes in degree of activation of VSMCs associated with the development of hypertension in SHR, the presence of several polymorphisms might be involved in overexpression of the p22phox gene in the vascular wall of the SHR. In another model of genetic hypertension, Kerr et al. described an association of the C242T p22 phox polymorphism in the p22 phox gene with the presence and extent of coronary artery disease. Thus, the possibility exists that NAD(P)H oxidase could play a role in patients with a greater cardiovascular risk.

Guzik et al. have reported a functional effect of the C242T p22phox polymorphism in the p22phox gene on NAD(P)H oxidase-driven \(-\text{O}_2^-\) production in the vascular wall of patients with atherosclerosis. Recently, Schachinger et al. described an association of the C242T p22phox polymorphism with coronary endothelial vasodilator function. Gottsmann et al. showed that the A640G polymorphism in the p22phox gene with the presence and extent of coronary artery disease was stronger in hypertensive than in normotensive subjects. Thus, the role of p22phox polymorphisms via NAD(P)H oxidase activity in human hypertension can be hypothesized.

### Conclusion and Perspectives

Arterial hypertension is associated with an enhanced vascular production of ROS, namely, \(-\text{O}_2^-\). Overactivity of NAD(P)H oxidase may be critically involved in such an alteration (Figure 2). Thus, this enzyme may play a role in endothelial dysfunction and vascular hypertrophy present in hypertension.
